Abstract

Introduction/aims: To prospectively determine the effects of Androgen Deprivation Therapy (ADT) on muscle mass and intramuscular proton diffusion on 3-Tesla MRI. We hypothesized that androgen deprivation therapy will cause a significant decrease in muscle mass and increase in Apparent Diffusion Coefficient (ADC).

Methods: A consecutive series of 16 physically active patients with proven prostate cancer treated with androgen deprivation therapy were prospectively recruited. MRI was obtained at 3 time points at two sites (gluteal and thigh regions) using a torso XL coil and a combination of 3-dimensional (3D) T2 Dixon and DWI sequences. Two trained readers measured muscle areas on axial reconstructions from 3D imaging and apparent diffusion coefficient of bilateral gluteus medius, iliopsoas and quadriceps muscles at fixed points. Linear mixed model was used to analyze the trends in each measurement along 3 time-intervals.

Result: Agreement between the readers was good to excellent for all measurements except area measurements of the bilateral iliopsoas muscles. On further mixed modeling, false discovery rate adjusted p-value did not show significant linear trend across any of the measurements (p>0.05). During at least six-month follow-up period, the patients denied any falls or fractures.

Discussion: In physically active men, androgen deprivation therapy in prostate cancer patients does not result in significant morphologic changes in pelvis and thigh muscle area or functional intramuscular diffusion in the short-term.

Introduction

The Global Cancer Observatory identified Prostate Cancer as the 2nd most commonly diagnosed cancer and 5th most deadly in men worldwide [1]. Androgens are important for the growth of the prostate gland, and men with elevated testosterone levels are shown to have an increased risk for developing prostate cancer [2]. Androgen deprivation therapy (ADT) has been used as a standard of care treatment for prostate cancer amelioration and it has shown to reduce adult prostatic epithelial cell growth and improve the quality of life in such patients [3,4]. Although ADT has been useful in the treatment of prostate cancer, it causes many adverse effects such as decreased bone density as confirmed by DEXA (dual energy X-ray absorptiometry) scans and increased fracture risk. Since the muscle-bone unit works in tandem and testosterone receptors are expressed on the myocytes, it has been proposed that myopenia and/or altered muscle function may predispose to a risk of increased falls and/or fractures [5]. However, to our knowledge, the effects of ADT on muscle mass or diffusion characteristics have not been studied to date. Our project aimed to...
prospectively determine the effects of ADT on the magnitude of intramuscular diffusion and muscle mass in physically active patients undergoing treatment for prostate cancer. We hypothesized that ADT will cause a significant decrease in muscle mass and increase Apparent Diffusion Coefficient (ADC) during the 6-month follow-up after initiation of ADT.

**Methods**
This study was a prospective cohort evaluation and all patients provided the informed consent. Institutional review board guidelines were followed, and the MRI studies were reviewed in a HIPAA compliant manner.

**Patients**
A consecutive series of 16 physically active patients who presented to our University hospital for the treatment of first-time diagnosis of prostate cancer from the October 2017-February 2020 were included. The patients were maintaining activities of daily living, exercised regularly (3x a week) and were counseled to keep active lifestyles. The inclusion criteria were men between the ages of 56-89 years, known prostate cancer, patients due to receive ADT and no contraindications for MRI.

**MRI acquisition:**
All studies were scanned on a 3T (Tesla) MR scanner (Ingenia, Philips) from L2 to proximal thigh using a torso XL coil and spine coils. A combination of 3-dimensional (3D) T2 Dixon and diffusion weighted imaging (DWI) sequences the patients received MR imaging at 3 time points: before ADT (time 0), and at 6 weeks and 6 months following ADT initiation, respectively. (Table 1).

**Data analysis**
A fellowship trained musculoskeletal (MSK) radiologist and another trained medical student reader under the close supervision of a different fellowship trained musculoskeletal radiologist performed all the measurements. Eight MRI scans of the total 48 scans were reviewed together by the two readers for the initial training. A week after the initial training, both readers reviewed the imaging independently and recorded the measurements blinded to each other’s reads and blinded to the prostate disease or ADT status. The muscle areas were measured on the axial isotropic reconstructions from 3D volume imaging and Apparent Diffusion Coefficients (ADC) were obtained from the corresponding slice axial DWI maps. The muscles were evaluated at fixed points and measurements were obtained from bilateral gluteus medius, iliopsoas and quadriceps muscles. The gluteus medius and iliopsoas were measured in the transverse plane at the level of the synovial part of the sacro-iliac joint and the quadriceps muscles were measured immediately below the lesser trochanter to ensure standardization. Image reconstruction and measurements were performed using HOROS software and employing a free hand ROI incorporating the whole muscle with careful exclusion of the regional fatty tissue (Figure.1 and Figure. 2). The data was recorded on a Microsoft excel spreadsheet. Qualitatively, muscle edema and fatty infiltration was assessed by a different senior MSK radiologist.

**Statistics**
Being a pilot prospective study, no power calculation was attempted. Agreement between the two readers was assessed us-

![Figure 2- Axial reconstruction from 3D T2 Dixon showing measurements of gluteus medius and iliopsoas](image2.png)
ing intraclass correlation coefficient (ICC) through one-way mixed effects models. ICC were interpreted as 0.0-0.2: poor; 0.2-0.4: fair; 0.4-0.6: moderate; 0.6-0.8: good; and greater than 0.8: excellent. Linear mixed models were used to test the difference in each measurement among the respective 3-time intervals. False discovery rate was reported. P<0.05 was considered statistically significant.

**Results**

There were 16 male patients (13 Caucasian, 3 African American) with ages ranging from 56-89 years (median 67 years), BMI median of 29.8 kg/m2, and PSA 4.57 (0.94, 7.31) ng/ml. The men exercised 3 times a week on average with no substantial change in habits before or after ADT therapy. There was a total of 48 MRIs (16 patients at 3 time points). All patients completed the whole imaging examinations. Serologically, as measured using standard institutional assays, the testosterone levels declined by week six in all patients that persisted on the 24-week check-up, confirming complete ADT response on the hormonal status. None of the patients reported a fall or fracture during the 6-month follow-up visit. Qualitatively, there was no edema like signal or noticeable fatty infiltration of muscles on the water map and in-phase maps of T2 Dixon imaging, respectively.

**Inter-reader correlation**

Among the 10 variables recorded, all measurements showed excellent inter-reader correlations, except for the areas of the left and right iliopsoas on T2 Dixon, which showed good correlation, confirming the validity of the measurements. The details of ICC and confidence intervals are depicted in Table 2.

**Linear Time trends**

The muscle area and ADC trends over the three time points have been illustrated in Figure. 3 and Table 3 shows the respective p-values. We tested for any trend. In other words, was there any difference between visits 1 vs 2, 1 vs 3 and 2 vs 3? Only one of the measurements (area of the right glutus medius on T2-dixon) yielded a raw P value less than 0.05. There was a marginal change (<10%) in muscle area on the second visit but it didn’t reach statistical significance. On further mixed modeling analysis, FDR adjusted p-value (q value) did not show a significant linear trend across any of the measurements.

**Discussion**

It has been shown that patients undergoing ADT therapy for the treatment of prostate cancer incur a loss of muscle mass and consequently muscle strength [6]. We didn’t find any significant change in muscle loss or alteration in diffusion characteristics. Other studies have revealed that loss of muscle density and attenuation as well as increase in fatty infiltration occurs in patients after ADT [7]. Ultimately, these deleterious effects on muscle could cause patients on ADT to exhibit a drastic change in physical function and quality of life [8]. Contrary to the reviewed literature, our study revealed no observable trend towards muscle loss as assessed by 3-D MR imaging. One difference in our cohort was that the men were physically active. Furthermore, prior research has indicated that there is an increase in fracture risk, loss of bone mineral density and increase in fall risk and frailty [9-11]. Our work did not investigate direct impact of ADT on bone properties but on the 6-month follow-up, none of our patients reported any falls or fractures.

This exploratory study results are limited by a small prospectively acquired sample with a risk of type II error, however ADT response was confirmed by suppression of serum testosterone levels. Larger studies in the future may confirm the results from this pilot study. A 2019 study shows that in patients undergoing ADT therapy for the treatment of prostate cancer, exercise has a protective effect on muscle mass, which could explain the lack of muscle loss in this work [12]. Another possibility is that there could be a change in muscle quality/microscopic composition; future studies can aim to use different MR sequence to analyze various other muscle properties, such as quantitative fat fraction and elasticity analysis. However, we did study the intramuscular diffusion. The muscle ADC values did not show significant trend towards increased or decreased diffusion. Microscopic muscle edema or altered architecture was expected but the results did not substantiate our hypothesis.

Figure 3- Measurements of T2-dixon area (A) and ADC (B) of right gluteus medius across three time points, which revealed no linear trend across any of the measurements.

The inter-reader analysis was good to excellent on all measurements. Uniform scanning using a single 3-T research scanner and isotropic 3D Dixon imaging facilitated excellent imaging resolution for standardized axial reconstructions and measurements.

The results may also be heavily influenced by the short-term follow-up, i.e., results are reported at 6 months of ADT, as previous studies analyzing the effects of ADT on bone health have reported these adverse changes occurring after one year [13]. Our results cannot be generalized to all prostate cancer patients undergoing ADT as none of our patients had metastasis and they all indicated good physical activity.

In future, the results of this pilot prospective study can be instantiated with larger cohort studies and comparison between physically active versus sedentary men could be performed. The results may guide institution of specific muscle strengthening protocols. We did not study muscle fat fraction as part of this article and such analysis may provide additional insights into temporal changes in muscle pathophysiology.

Conclusion
This pilot prospective study showed that there is no observable trend in muscle area loss or altered intramuscular diffusion in physically active prostate cancer patients undergoing ADT. The study establishes that MRI markers of skeletal muscles are not susceptible to ADT therapy in the short-term and suggests that specific muscle strengthening protocols might not be critical in physically active men during the follow-up visits to prevent future falls.
